#### Summary

This paper examines the role of pro-social behavior as a mechanism for the establishment and maintenance of cooperation in resource use under variable social and environmental conditions. By coupling resource stock dynamics with social dynamics concerning compliance to a social norm prescribing non-excessive resource extraction in a common pool resource (CPR), we show that when reputational considerations matter and a sufficient level of social stigma affects the violators of a norm, sustainable outcomes are achieved. We find large parameter regions where norm-observing and norm-violating types coexist, and analyze to what extent such coexistence depends on the environment.

## Abstract

This paper examines the role of pro-social behavior as a mechanism for the establishment and maintenance of cooperation in resource use under variable social and environmental conditions. By coupling resource stock dynamics with social dynamics concerning compliance to a social norm prescribing non-excessive resource extraction in a common pool resource (CPR), we show that when reputational considerations matter and a sufficient level of social stigma affects the violators of a norm, sustainable outcomes are achieved. We find large parameter regions where norm-observing and norm-violating types coexist, and analyze to what extent such coexistence depends on the environment.

# 1 Introduction

Local and global ecosystems are under growing pressure worldwide, and beyond any doubt their sustainable management cannot be achieved without the stakeholders' cooperative efforts. History has taught us that the livelihood of our species is inextricably related to our ability to cooperate, in the sense of restraining use of natural resources to sustainable levels, rather than giving in to excessive resource appropriation. However, depending on the characteristics of the system at hand, tensions between individual and collective good may undermine such norm of restraint. CPRs where beneficiaries of the resource have open access to it are a notable case of appropriation externality paving the way for short-sighted resource utilization: all agents would be better off if they collectively restrained extraction, but if the impact of one's action on the resource stock is ignored, it is individually rational not to do it. Thus, maintaining cooperation against the myopic self-interest of a potentially large fraction of individual users unwilling to restrict their behavior for the collective good, and despite growing environmental pressure, is a challenging task that often depends on a multitude of factors, as both successful and unsuccessful environmental management has shown. Nevertheless, field work, controlled experiments involving participants playing stylized games aimed at reflecting the trade-offs inherent in these social dilemmas (e.g., CPR and public good games), as well as casual observation, suggest that human beings are able to overcome the obstacles to cooperation in a variety of settings.

Many explanations have been proposed to account for the widely-observed departures from the rational-agent models' predictions of collectively inefficient resource management in the absence of regulatory institutions. Established mechanisms that have been advanced to account for the evolution of cooperation are, following Nowak (2006): kin selection (the inclination of related individuals to engage in cooperative behavior), direct reciprocity (the "I will scratch your back if you scratch mine" attitude towards reciprocating), indirect reciprocity (I will scratch your back because someone else scratched mine), network reciprocity (spatial structure is assumed to allow for unevenly mixed populations where some individuals interact more frequently than others) and multilevel selection (where the population is divided into groups whose members are allowed to enact different strategies depending on whether they are matched with own-group members or with members of other groups).<sup>1</sup>

These mechanisms have been shown to suffice for the evolution of cooperation in Prisoner's Dilemma games whenever the payoffs are such that the benefit-to-cost ratio of the cooperative action exceeds a certain mechanism-specific threshold. While the above mechanisms incorporate some of the empirically observed factors that influence the success of collective action, such as the topology of interactions and group size, we postulate that the link to other important drivers of cooperation needs to be made

---

<sup>1</sup>More recently the term of assortment, indicating the "degree of segregation of different types of individuals into different groups" as Pepper (2007) puts it, has gained consensus among scholars for its generality. See van den Bergh and Gowdy (2009) and Fletcher and Doebli (2009) for recent contributions to the group selection debate. It should be noted that many other mechanisms with a certain degree of overlapping characteristics have been employed in various disciplines to highlight the tension between in-group and outsiders; among others, parochialism (Choi and Bowles 2007, ) and homophily (Currarini et al. 2009).

explicit if one wants to attempt to bridge the gap between the empirical findings on commons management and the theory.

In the present paper we aim to analyze a simple model that departs from the full-rationality paradigm placing emphasis on two such drivers: the presence of individuals with other-regarding preferences and the conformist pressure in the direction of norm compliance arising from fear of community disapproval. Laboratory experiments, such as Fehr and Fischbacher (2002) and Maier-Rigaud et al. (2008), respectively suggest that both are relevant, while contributions from social psychology (Cialdini, 1984) and the empirical literature on the commons stress the importance of the second driver. For what concerns the empirical findings, the work of Ostrom (1990 and 2007) has suggested that many CPRs have escaped the trap of the tragedy of the commons by being managed in a self-organizing manner with mechanisms such as rules, norms and graduated sanctions favoring cooperation among users. Such mechanisms may result from the repeated interactions of the resource users: given suitable conditions, for example in terms of knowledge of the ecosystem by the community members, they could develop a sense of what behavior is acceptable with respect to resource use.

The enforcement of the proper behavior or sanctioning thereof will take different forms depending on the features of the social and resource system at hand. One increasingly studied class concerns social norms. Following the work of Sethi and Somanathan (1996), much attention has been given to the role of costly punishment of defectors in promoting cooperation; recent contributions aimed at extending their setup have been proposed by Noailly et al. (2007) and Sethi and Somanathan (2006). While both retain the three agent types format, with defectors, cooperators and enforcers bearing the costs of punishment, the former allow for spatial structure in the interactions, and the latter introduce a concern for reciprocity among the agents. Yet, the empirical literature on the commons argues that a variety of sanctioning mechanisms against norm violators are utilized to promote successful management of irrigation systems, fisheries, pastures and forests (Ostrom 1990, Baland and Platteau 1996, ch.8 and 11). Moreover, as suggested by the literature on social capital (Bowles and Gintis 2002, Osés-Eraso and Viladrich-Grau 2007, Iwasa 2009), resource appropriators embedded in a social context can often rely on a wider set of tools than the traditionally considered costly sanctioning of free-riding behavior. When the result of one's actions is observable, be it the resource extraction itself or the outcome of a productive activity which is dependent on the latter, field and experimental evidence suggests that individuals belonging to a community act more cooperatively than when in isolation, as a result of their exposure to social reprobation.<sup>2</sup>

In the present paper we focus on one such mechanism, which we term equity-driven ostracism, by which we refer to the exclusion of norm-violators from community privileges or social acceptance.<sup>3</sup> The underlying idea is that appropriators' decisions about how much effort to exert in the extraction of a natural resource are based on

---

<sup>2</sup>According to Gowdy (2008): "Experimental results from behavioral economics, evolutionary game theory and neuroscience have firmly established that human choice is a social, not self-regarding, phenomenon. [...] Human decision-making cannot be accurately predicted without reference to social context". Recent evidence on the importance of the social context in guiding individual behavior is found in Fehr and Fischbacher (2002) and Akerlof (2007).

<sup>3</sup>The term ostracism is to be read here as a refusal of help towards norm violators rather than a physical displacement of the latter, as will be clear from the following discussion.

the prevailing norms that have emerged in the community, in addition to the usual efficiency considerations. As a result of the compliance decision with respect to the norm, those who deviate (the defectors) may be refused resources and support by those who comply. As an example, the ostracism costs considered here could be thought of as originating from destruction of defector’s crop by the cooperators, or simply from refusal of help by the community towards a defector in the form of denial of loan of machinery or means of transportation needed to take the harvest to the market. The rationale for this behavior is that, in a community of individuals who share access to a natural resource, those who restrain their extraction level to the socially acceptable level will not show the same level of support they have for fellow cooperators, when it comes to defectors. The inherent tradeoff between unrestricted profit seeking and norm adherence can be visualized in Figure 1.

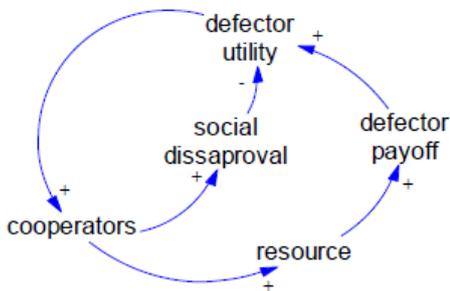

Figure 1: Interactions between the composition of the population, resource abundance and norm enforcement

This schematization allows us to highlight the ever-changing conditions faced by appropriators choosing between extraction patterns. If the number of cooperators increases, so will the resource stock, favoring the defectors the most (due to their behavior being unrestricted by the norm) and rendering opportunistic behavior more profitable, thus posing unfavorable selective pressure on the cooperators’ population. These trends are captured by the outer arrows originating from the cooperators in Figure 1, with favorable (unfavorable) changes marked with a “+” (“-”) sign to the right of the arrows. However, as shown by the inner arrows, an increase in the number of cooperators also leads to greater social disapproval towards norm violators, as fewer defectors will face ostracism by a larger community of norm followers denying them the benefits of cooperation. We implement this simple mechanism in an evolutionary framework in order to allow for departures from optimizing behavior as prescribed by Nash equilibrium. Namely, rather than assuming that the resource appropriators instantaneously maximize their material well-being in a repeated-interaction model with discounted future, we let evolution gradually shape the proportion of agents playing a given strategy by favoring the more successful one. The advantage of this bounded rationality approach (imitate the successful behavior with inertia) is that it avoids the downfalls of the multiplicity of equilibria and lack of robustness to noise, while retaining the behavioral tendency to move in the direction of a more profitable strategy.<sup>4</sup>

<sup>4</sup>For a critique of the commonly used approaches in the economic analysis of common property,

The results of the analysis, presented in Section 2, suggest that both monomorphic and dimorphic populations emerge: that is we find stable full compliance and full defection equilibria as in Sethi and Somanathan (1996), but also mixed equilibria where both types coexist. In Section 3 we investigate the impact of variation in environmental conditions, by allowing for variability in the rate of resource regeneration as well for a multiplicity of extraction strategies subject to evolutionary pressure. Section 4 provides conclusive remarks.

## 2 A model of coupled socio and resource dynamics

We examine the role of other-regarding behavior as a mechanism for the establishment and maintenance of cooperation in resource use under variable social and environmental conditions. This is done by modeling the evolution of compliance to a social norm prescribing conformity to an agreed extraction level, and its coevolution with a CPR stock dynamics. The coupled dynamics allows us to investigate the stability of cooperation in a population of resource users who have symmetrical access to it and are not only concerned with own yield from productive use of the resource, but also with their status with respect to other community members, as acceptance to the community is at stake. Payoff comparisons (e.g. with respect to crop size) lead to ostracism of the norm violators by the cooperating community, which denies defectors the benefits of resource and knowledge support, imposing losses on them that may offset those incurred by cooperators when restricting resource extraction practices to more sustainable ones. That is, individuals face a trade-off: on the one hand they can extract resource at individually optimal (but socially detrimental) levels without restricting usage, or on the other hand they can constraint themselves to a socially agreed upon acceptable level. By doing so, their conventional materialistic pay-off is necessarily below that of the non-cooperating agents, because of the above mentioned lower extraction and consequently reduced yield (which is increasing in the extraction effort). However, violators of the social norm, insofar as they are recognized as such, are penalized by being excluded from the help of the cooperating community (e.g. in bringing the yield to the market): such defectors-specific ostracism costs have a variable magnitude that depends on the relative size of the cooperating community, since at low frequencies of cooperative agent types, the defectors will incur only mild consequences, but at high enough frequencies of cooperators, the former may incur high enough ostracism costs that it will be advantageous to be part of the sustainable community. Lindbeck (1997) suggests this network good property of norms: “a social norm is felt more strongly, the greater the number of individuals who obey it. Thus, the adherence to a social norm is a choice conditioned on other individuals’ adherence to the same norm. The psychological explanation for this type of behavior may be either that disapproval from others is more troubling if expressed by many people than by few or that other people’s behavior is assumed to signal information about what is proper or potentially successful behavior.” Agents are considered as productive units (one can think of an agent as an individual or a family), whose share of the total production (e.g. the size of their crop) is proportional to the share of their

---

see Sethi and Somanathan (2006).

appropriation effort with respect to the aggregate effort. Their source of revenue is assumed to positively depend on two factors: the availability of an indispensable resource for both productivity and livelihood, such as water broadly conceived, and the amount of effort agents put in their productive (income-generating) actions, which is (positively) affected by resource abundance. That is, both the resource and the appropriation effort enter in the agents' (twice-continuously differentiable) production function  $f(E, R)$ , where  $E$  represents the community effort (e.g. the aggregate water usage) resulting from the actions of the  $n$  agents comprising it, and  $R$  is the resource available to the community (which may either be entirely consumed in a given time period, or saved in part for future consumption). Formally, letting  $e_i$  be the individual effort (i.e. his/her resource uptake), which can either take value  $e_c$  for a cooperator or  $e_d$  for a defector, with  $e_c < e_d$  due to the more sustainable practices of the former, the following inequalities are therefore assumed to hold:  $\frac{\partial e_i}{\partial R} > 0$ ,  $\frac{\partial f(E, R)}{\partial E} > 0$ ,  $\frac{\partial f(E, R)}{\partial R} > 0$ ,  $\frac{\partial^2 f(E, R)}{\partial E^2} \leq 0$ ,  $\frac{\partial^2 f(E, R)}{\partial E \partial R} \geq 0$ ,  $\frac{\partial (f(E, R)/E)}{\partial R} \geq 0$ .<sup>5</sup> Let's go in further detail about the model. It is useful to consider again the joint level of effort  $E$  resulting from the actions of the  $n$  agents choosing their level of effort  $e_i$ ; letting  $f_c \in [0, 1]$  be the proportion of cooperators, we have  $E(f_c, R) = f_c * n * e_c(R) + (1 - f_c) * e_d(R)$ . We assume that  $n$  is fixed, so that entry is ruled out, while  $f_c$  is continuous and non-negative, and see that for positive levels of  $e_c$  and  $e_d$ , the total level of effort is a decreasing function of the frequency of cooperators. The two effort levels, that are here assumed to sum up the behavioral inclinations of all agents in the community, are bounded below by the collectively efficient resource use level and above by the static Nash equilibrium level. This amounts to require that both agent types follow practices that are above those that would maximize collective utility, but to a different extent: the defectors ignore the emergent social norm prescribing the socially agreed-upon acceptable individual effort  $e_c$  by choosing a greater level  $e_d$  (up to the individually rational but inefficient Nash equilibrium level resulting in excessive resource use), while cooperators stick to  $e_c$ , which, as a special case, may coincide with the level that efficiently trades off the individual incentive towards high or uncoordinated resource utilization with the social need to impose constraints to guarantee a sustainable use (which ultimately benefits the individuals). Letting  $E_{eff}$  be the community efficient level,  $e_{eff} = E_{eff}/n$  the corresponding individual efficient level under symmetry, and  $e_{Nash}$  be the Nash equilibrium level of effort, we formalize what stated above as:  $e_{eff} \leq e_c < e_d \leq e_{nash}$ .<sup>6</sup> These conditions guarantee that, at the aggregate level, positive rents from productive use of the resource can be maintained. That is, the average product of labor is assured to be above the opportunity cost of labor independently from the share of defectors, providing the incentive for agents

<sup>5</sup>These assumptions are generally employed in the literature concerning resource exploitation in a common pool resource, such as, for example, a fishery where a community of fishermen have access to it and each can decide on the individual level of exploitation (jointly affecting the sustainability of the resource utilization). Cf. Sethi, Somanathan (1996), Xepapadeas (2005) and Osés-Eraso, Viladrich-Grau (2007).

<sup>6</sup>Note that a direct implication of such constraints is that  $E_{eff} \leq E \leq E_{nash}$ . See Dasgupta and Heal (1979, 55-60) for a comprehensive treatment of exhaustible resources, and Osés-Eraso, Viladrich-Grau (2007, 398) for the description of a process leading to the prevalence of one representative strategy for each type of behavior. In §2.3 we restrict attention to  $e_{eff} = e_c$ , i.e. we hypothesize that the emergent norm prescribes collectively optimal extraction levels, but, differently from the cited literature, we consider what happens for different magnitudes of defection (ranging from slightly above  $e_c$  to Nash effort levels).

to increase their resource use (as they can earn positive profits for positive levels of effort). It is further assumed that  $f(0, R) = 0 = f(E, 0)$  for the obvious reason that strictly positive levels of effort and resource are required to generate income via the function  $f(E, R)$ . The individual payoff given resource  $R$  and the behaviour of all community members is:

$$\pi_i(e_1, e_2, \dots, e_n, R) = p \frac{e_i}{E} f(E, R) - we_i \quad (1)$$

Letting  $R^*$  the equilibrium resource level (to be defined more precisely below) and  $\Pi(e_1, e_2, \dots, e_n, R) = \sum_{i=1}^n \pi_i = f(E, R) - wE$ , the optimal solution to the aggregate payoff maximization problem is given by  $E_{eff} = \arg \max_E (\Pi)$ , and satisfies  $f'(E_{eff}, R^*) = w/p$ , where  $w/p$  is the ratio between the opportunity cost of labor  $w$  and the world price  $p$  of the resource-absorbing good produced.<sup>7</sup>

For the sake of compactness and to stress that the payoff to  $i$  is only indirectly affected by the others' choice of effort (through  $f(E, R)$ ), we will use the notation  $\pi_i(e_i, R)$  below. We know that, due to the negative appropriation externality arising from the disconnect between individual extraction and knowledge of its effect on the resource stock, the aggregate level of effort in equilibrium if all agents play according to the Nash equilibrium will be above  $E_{eff}$  as each individual will treat the resource stock as fixed and therefore extract more resource than is efficient.

## 2.1 Resource dynamics

Let's turn to the resource dynamics and its interaction with the social dynamics occurring as a result of human action. Focusing on the ecological features governing the resource first, in the absence of human appropriation we are left with the constant resource inflow ( $c$ ) and a term dependent on the resource level ( $R$ ) as well as on three parameters ( $d$ ,  $k$  and  $R_{max}$  governing the discharge, curvature and maximum storage capacity) to account for a positive rate of growth up to the  $R_{max}$  (e.g. the upper limit in a groundwater aquifer's intake), which becomes negative beyond that level. We follow Ibañez (2004) for what concerns the above mentioned ecological variables, and include the aggregate resource use by the individuals ( $ER$ ), which appear as the last term of the following equation:

$$\dot{R} = c - d \left( \frac{R}{R_{max}} \right)^k - ER \quad (2)$$

$\dot{R}$  indicates the time derivative of the resource stock, i.e. its overall rate of change resulting from the interaction of replenishment, discharge and utilization. Note that the resource replenishment rate, which is captured by the first term in the right-hand side of (2), is exogenous with respect to the frequency of cooperators (and consequently the resource extraction), which affects instead the second and last terms, respectively representing the limits to resource accumulation (due to stock effects) and the resource utilized by the community for productive tasks such as irrigation.

---

<sup>7</sup>An example of a function guaranteeing the existence of an optimal solution, at each point in time, to the aggregate payoff maximization problem, is the familiar Cobb-Douglas formulation with decreasing returns to scale:  $f(E, R) = E_i^\alpha * R_i^\beta$ ,  $\forall E \geq 0, R > 0$  and  $\alpha + \beta < 1$ .

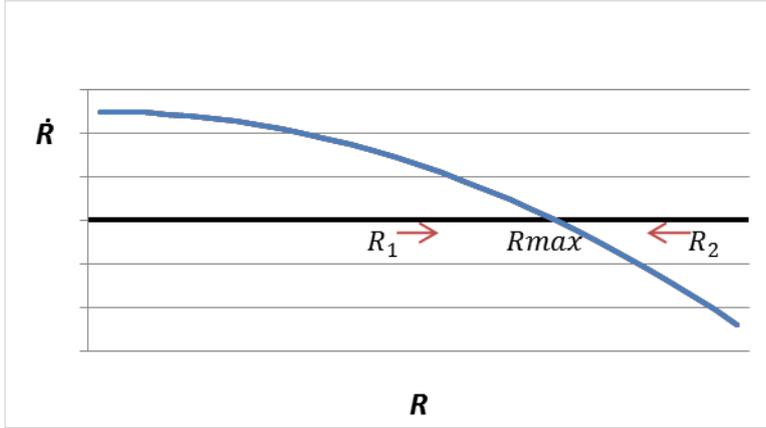

Figure 2: The rate of change of the resource as a function of its stock, in the absence of appropriation

For the sake of concreteness, one can think of agents extracting water for irrigation purposes from an underground reservoir subject to replenishment due to snowmelt or rain, whose ability to store water has a natural upper bound ( $R_{max}$ ). Beyond it, discharge occurs at a rate which is increasing in the deviation from the maximum storage capacity. Two facts are worth noting at this point. First, in the absence of extraction, the equilibrium resource level will settle on  $R_{max}$ . This since, if the stock at one point in time is to its left ( $R_1$  in Figure 2), the resource will continue to accumulate ( $\dot{R} > 0$ ) until  $R_{max}$  is reached; if instead the stock at a given time is to its right ( $R_2$ ), discharge will bring it back to  $R_{max}$ . Secondly, due to human extraction, the equilibrium resource level  $R^*$  will actually be below the maximum storage capacity.<sup>8</sup> With these notions in mind, we are now ready to shift attention to the strategies and tradeoffs faced by the two types of agents.

## 2.2 Equity-driven ostracism

Recall that equation (1) represents the amount an individual appropriator can make based on his/her effort and the yield, abstracting from costs originating from social stigma (and the consequential ostracism imposed by the community on defectors). This amount is proportional to the aggregate payoff (itself a function of the market price of the final yield  $p$  and of the production function  $f$ ), in relation to the individual's resource uptake  $e_i$ , which positively enters in the first term in the right hand side of (1) and negatively in the second term representing the work-related costs. To account for the costs accruing to norm violators when identified by the community

<sup>8</sup>In fact, due to the boundary conditions on the effort levels and (1), the equilibrium resource level will satisfy the condition  $0 < R_{nash} \leq R^* \leq R_{eff} < R_{max}$ , where  $R_{nash}$  is the resource level corresponding to monomorphic Nash behavior (a population comprised solely of individuals maximizing profits taking  $R$  as exogenous), and  $R_{eff}$  is the socially optimal level that would obtain if all individuals jointly maximized collective welfare (effectively internalizing the appropriation externality). Therefore, depending on the population composition, and consequently on the aggregate extraction, the equilibrium level  $R^*$  will be closer to one of the above two boundaries: in a dimorphic population comprised of a majority of defectors,  $R^*$  will be close to  $R_{nash}$ , while its distance from  $R_{eff}$  will be shorter the more the number of cooperators. Note that according to the above inequality, even under full defection there is a positive resource value ( $0 < R_{nash}$ ) guaranteeing the assumed positive rents.

as such, we incorporate them as shown:

$$\begin{aligned}
U_i &= \pi_i - \omega(f_c) * \max \left\{ \frac{\pi_i - \pi_c}{\pi_d}, 0 \right\} \\
&= e_i \left( p \frac{f(E, R)}{E} - w \right) - \omega(f_c) * \max \left\{ \frac{e_i - e_c}{e_d} \left( p \frac{f(E, R)}{E} - w \right), 0 \right\} \quad (3)
\end{aligned}$$

This translates to a payoff to a norm complier (cooperator) which is simply given by

$$U_c = \pi_c \quad (4)$$

while a norm violator will be subject to<sup>9</sup>:

$$U_d = \pi_d - \omega(f_c) \frac{\pi_d - \pi_c}{\pi_d} \quad (5)$$

Recalling the tradeoffs highlighted in Figure 1, one sees from the comparison of (4) and (5) that, for what concerns the productivity, defectors have an advantage ( $\pi_d > \pi_c$ ) as a consequence of their higher appropriation; due to stock effects, such productivity advantage positively depends on the relative abundance of cooperators. On the other hand, defectors are deprived of the communitarian social capital and experience a reduction to the income generated with resource-intensive productive activities, while cooperators can also tap in the community for help and thus enjoy the entire yield  $\pi_c$ . As compliance to the social norm is voluntary and observable, these benefits are denied to non-members; further, it is assumed that the community ostracism function  $\omega(f_c)$  is increasing and concave in the number of participants (abiding to the social norm), due to the network good characteristics highlighted at the beginning of this section. Notice also that it multiplies the ratio between the payoff difference and the defector's payoff, to model a reaction by the cooperators which is stronger the larger the relative intensity of the defection (leading to a larger negative productivity gap of norm followers with respect to defectors).

### 2.3 Evolution of ostracism

The analysis of the behavioral evolution of agents facing decisions on their resource practices is conducted by means of replicator dynamics. By so doing, we avoid the complete rationality requirements typical of models of optimization, while retaining (myopic and lagged) convergence towards better outcomes due to the imitation of successful behavior. Such an approach is particularly well-suited to the analysis of the evolution of norm adoptions as it allows to focus on emergent phenomena without being confined, as is the case for neoclassical analysis, to equilibrium outcomes and representative agents solely described by their optimizing behavior. Here, rather than rationally best responding to the actions of others as in Nash equilibrium, individuals

<sup>9</sup>Raakjær Nielsen and Mathiesen (2003) found, among the five more relevant factors affecting compliance in Danish fisheries: the economic gains to be obtained from noncompliance, deterrence and sanctioning costs, and the presence of “norms (behaviour of other fishers) and morals”. In (5), the gains appear in  $\pi_d$ , while the losses due to the sanctions and the comparison with others are captured by the product  $\omega(f_c)((\pi_d - \pi_c)/\pi_d)$ . Notice that the strongest action against defectors will be taken when the number of cooperators is largest (i.e.  $\pi_d - \pi_c$  and  $\omega(f_c)$  are highest), while when defection is spread all over it will go almost unnoticed (i.e.  $\pi_d \approx \pi_c$  and  $\omega(f_c)$  is low).

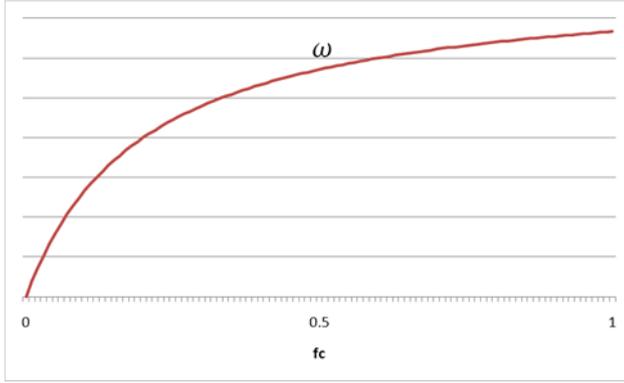

Figure 3: The ostracism function. A higher  $f_c$  (larger cooperator community) increases the ostracism's severity. Here we plotted  $\omega(f_c) = \delta \frac{f_c}{\lambda + f_c}$ , where  $\delta$  is a scaling factor that will be used in Section 3 to model the community stringency in enforcing the norm

update their strategies when given the option, and switch to the strategy of the agent with which they are randomly matched if the utility of the latter is above the individual's.<sup>10</sup> It can be shown that such strategy revision takes place with a probability which is proportional to the payoff difference with respect to the average: if, for example, the average is well above the payoff of a cooperator, he or she is more likely to notice the benefits from switching than if the average was only slightly above the agent's payoff. Formally, this leads to the 2-strategy replicator dynamics, which combined with (3) yields, after rearranging terms:

$$\dot{f}_c = f_c(U_c - \bar{U}) = f_c(1 - f_c)(U_c - U_d) = f_c(1 - f_c) \frac{\pi_d - \pi_c}{\pi_d} (\omega(f_c) - \pi_d) \quad (6)$$

The dotted superscript stands for time derivative: equation (6) models the evolution of cooperating types. We are interested in the nullclines satisfying  $\dot{f}_c = 0$ : in addition to the monomorphic outcomes characterized by one type of agent only, we look for solutions in which positive amount of both types coexist (with  $f_c \neq 0$  and  $f_c \neq 1$ ). That is,

$$(f_c^*, R^*) : \theta(f_c^*, R^*) = \frac{\pi_d(e_d, R^*) - \pi_c(e_c, R^*)}{\pi_d(e_d, R^*)} (\omega(f_c^*) - \pi_d(e_d, R^*)) = 0 \quad (7)$$

The system described in (2)-(6) can be represented in the  $(\mu, f_c)$  parameter space, where  $\mu$  is the effort multiplier between a cooperator and a defector; for instance, in Figure 4,  $\mu = 2$  signifies that the defector's effort is twice the cooperator's effort, while  $\mu_{nash}$  signifies that  $e_d = e_{nash}$ . While only one type of defector is considered at a time (as well as one cooperator type satisfying  $\mu = 1$  and extracting at the collectively efficient level), Figure 4 allows one to investigate the prospects for cooperation for different levels of defection. We deem useful to condense this information in the compact graphical tool below, since, depending on the social and ecological characteristics of the system under consideration, the concept of defection may vary greatly. For example, in a relatively well-established community (both in a temporal

<sup>10</sup>See Taylor and Jonker (1978) or Weibull (1995) for details on replicator dynamics.

and spatial dimension), it may be reasonable to expect that a clear and shared notion of norm violation has shaped over time, and therefore that defectors are somewhat cautious and refrain from extracting at a very high level (such as  $\mu_{nash}$ ). On the other hand, a relatively new community, or one which is more spatially fragmented, may be characterized by higher defection levels (e.g.  $\mu > 2$ ), due to the lack of clarity over what the acceptable behavior is. Figure 4 illustrates the fate of cooperation for different definitions of defection, i.e.  $\mu$  levels, in order to capture these different cases in a comprehensive manner. Given the positive value of the first three terms on the right

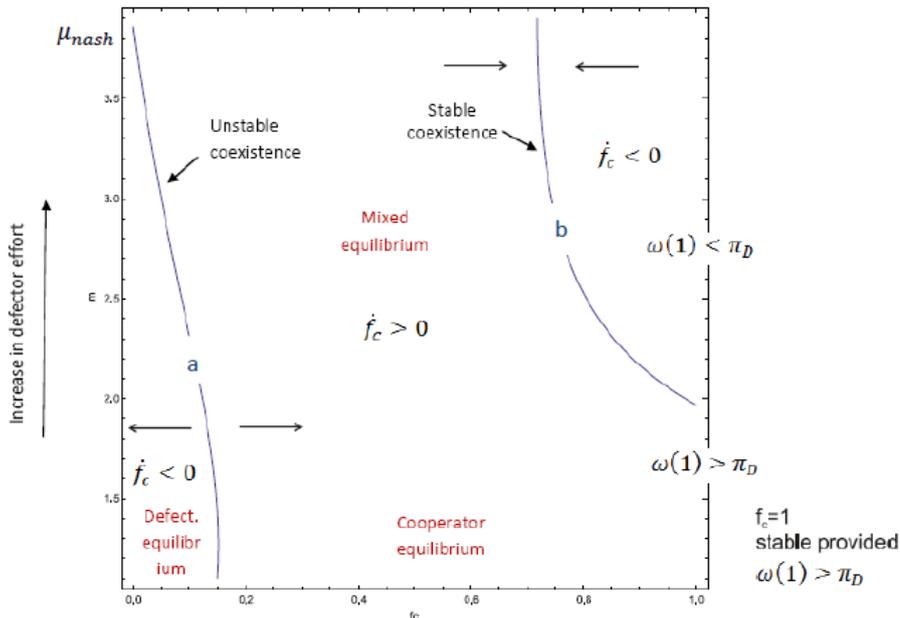

Figure 4: The  $\omega(f_c^*) = \pi_d(e_d, R^*)$  loci guaranteeing coexistence of types.

hand side of (6), (with the exception of degenerate cases), it is straightforward that the proportion of cooperators will increase ( $\dot{f}_c > 0$ ) provided that  $\omega(f_c) > \pi_d(e_d, R)$ . Where the system ultimately stabilizes depends on the initial conditions: however, as we can readily observe from Figure 4, we have both areas characterized by the presence of one type of agent only and areas of coexistence. Note that with an increase in cooperators the ostracism  $\omega(f_c)$  increases, but so does the defector payoff  $\pi_d(e_d, R)$ , because productivity increases with an increase in  $f_c$ ; such interaction causes non-trivial dynamics that are analyzed here under the evolutionary lens provided by the replicator equation. In the Appendix we derive results from the stability analysis based on the linearization matrix  $J$  of the system (2)-(6), which shows that:

- a) the Defector equilibrium is a stable attracting fixed point;
- b) the Cooperator equilibrium is stable so long as the defector's payoff is bounded above by the full compliance ostracism costs, i.e.  $\omega(1) > \pi_d$ .

What happens for intermediate frequencies of cooperators? From (7) we know that, if it exists, the coexistence equilibrium must satisfy  $\omega(f_c^*) = \pi_d(e_d, R^*)$ . Inspection of the curves in Figure 4 allows one to assess the qualitative features of the

system resulting from the above condition: to the left of locus  $a$ , i.e. for low initial  $f_c, \omega(f_c) < \pi_d(e_d, R)$ , so the system will evolve towards the stable defector equilibrium independently of  $\mu$ . If, for instance, we consider defectors who extract resource according to the Nash rule ( $\mu_{nash} : e_d = e_{nash}$ ), the equilibrium will be characterized by  $\omega(0) = 0 < \pi_d(e_d, R_{nash})$  (see footnote 8). To the right of locus  $a$ ,  $\omega(f_c) > \pi_d(e_d, R)$ , so the community of appropriators following the restrictive norm will grow larger. The system will transition towards the cooperator equilibrium when the effort difference between cooperators and defectors is not too large (low  $\mu$ ), as the above inequality will continue to hold until stable monomorphic cooperation obtains, with  $\omega(1) > \pi_d(e_d, R_{eff})$  (see Figure 4 and footnote 8). When instead effort differences are large, the proportion of cooperators will keep increasing up to a point where  $\omega(f_c^*) = \pi_d(e_d, R^*)$ : At this point population composition does not change any longer and the mixed equilibrium persists. The same obtains when starting to the right of locus  $b$ ; in other words,  $b$  is a stable locus of mixed equilibria. Note that this is not true for locus  $a$ , which is unstable.

### 3 Model extensions with variable resource replenishment rate and strategy competition

To extend the above analysis to conditions of variable resource inflow or multiple extraction strategies we developed agent-based simulations (ABM). The basic setup of the ABM closely follows the evolutionary game theoretic model, although in discrete time: individual agents are randomly matched for payoff comparison and strategy updating as in the replicator dynamics above. A time step equals the length of one replenishment cycle for the resource. Agents extract resources according to their effort strategy and produce a good that provides them with the respective payoff. At each time step two agents are matched randomly to update their utilities and strategies. When a positive payoff difference signals defection, the defector will be ostracized with a magnitude proportional to the share of cooperators in the population and the relative payoff difference between the two opponents, in equation (3). Subsequently, when his/her utility is below that of the opponent, an agent  $i$  updates his strategy by imitating the strategy of the opponent  $j$  with a probability equal to the utility difference (cf. Morgan, 2003). Letting  $\Delta_i = U_i - U_j$ ,

$$\text{if } \Delta_i < 0 \Rightarrow e_i \rightarrow e_j \text{ with probability } \frac{U_i - U_j}{|U_i| + |U_j|} \quad (8)$$

We simulate the evolution of the population from an initial population composition and a specified effort difference between cooperators and defectors. Figure 5 shows the result of multiple simulation runs with different initial conditions and effort differences. Note that the effort difference represented on the y-axis is fixed within each simulation, while the initial proportion of cooperators represented on the x-axis is only the initial value with the final value presented in the pixels in the graph. Each square represents the average proportion of cooperators of the last 500 time steps of each run across 30 runs. With low initial proportion of cooperators and low effort

difference the system converges to a Defector equilibrium. A Cooperator equilibrium emerges when initial proportions of cooperators are at least 15% and the effort difference not too large. Once effort differences increase above approximately 2 (i.e. defector effort is twice the cooperator effort) the system converges to a mixed equilibrium. When effort differences increase even more the mixed equilibrium covers the entire parameter range and the frequency of cooperators in the mixed equilibrium decreases. The simulation results are consistent with the analytical model presented in Figure 4 except for the region in the upper left corner, where in the simulations the stable defector boundary equilibrium disappears. Here, the transient dynamics characterized by stochastic updating and the discreteness of the individual agents create a situation where the resource is depleted faster than the single cooperator has a chance to update his strategy to defection. In the game theoretic model with high effort differences the unstable boundary to the mixed equilibrium approaches the stable all defector equilibrium and thus small perturbations, e.g. due to the stochastic updating, can shift the system to the mixed equilibrium.

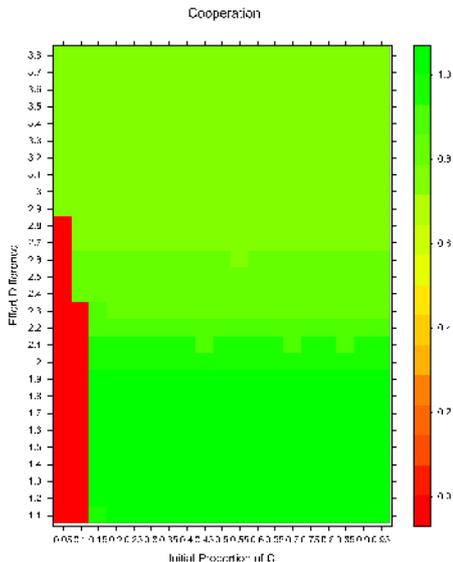

Figure 5: Frequency of cooperators for different initial  $f_c$  and different  $\mu$ . Red indicates a Defector equilibrium, dark green indicates a Cooperator equilibrium. Each square represents the average of 10 different runs

### 3.1 Variable Inflow

In reality resource flows such as water flows in a landscape are rarely constant. Particularly in semi-arid regions water availability can vary drastically within and between years. Climate change is likely to increase this variability and lead to more frequent extreme events. This puts additional pressure on water users that have to cope and adapt to changing resource conditions. To assess the effect of inflow variability on the stability of cooperation we developed an ABM with variable inflow to the resource pool. The modified resource dynamics are given in the following relationship:

$$R_{var,t+1} = R_{var,t} + c_{var,t+1} - d_{var,t+1} * (R_t/R_{max})^2 - E_t R_t \quad (9)$$

where  $c_{var,t}$  (for  $t = 1, \dots$ ) are independently distributed pseudorandom Gaussian values standardized to have mean  $c$  and standard deviation  $\sigma$ . The baseline discharge rate  $d_{var,t}$  is set equal to the inflow to maintain a carrying capacity equal to  $R_{max}$ . Figure 6 shows that with an increase in variability of inflow to the common resource pool, the percentage of cooperators in the mixed equilibrium increases, thus indicating an advantage for cooperators. We explain the disadvantage for the defectors with the concavity of the resource function at  $\dot{R} = 0$  (see Figure 2), which leads to a decrease in the average resource volume with inflow variability. Recalling the analysis of Section 2, letting  $\tilde{R} < R$  be the perturbed resource volume at time  $t$ , we note that the corresponding payoff  $\tilde{\pi}_i(e_i, \tilde{R}) < \pi_i(e_i, R)$ , which implies that  $\tilde{\pi}_d(e_d, \tilde{R}) < \pi_d(e_d, R)$ . However, the ostracism function is independent of  $R$ , so the loci satisfying  $\omega(f_c^*) = \pi_d(e_d, \tilde{R}^*)$  will shift rightward ( $a$  and  $b$  in Figure 4). Put differently, a lower average resource volume leads to reduced payoffs for both defectors and cooperators. Defectors, however, are also subject to ostracism which is only a function of the frequency of cooperators and thus is not affected by inflow variability. The decrease in defector payoff with constant ostracism costs decreases the frequency of defectors in the mixed equilibrium. With respect to the phase plot of the game theoretic model, the simulation results indicate that the loci of stable coexistence ( $\omega(f_c) = \pi_d$ ) shift right and closer to the unstable all cooperators boundary equilibrium (top right corner in Figure 4).

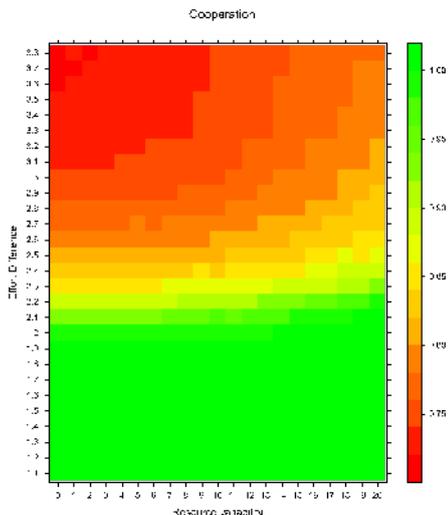

Figure 6: Frequency of cooperators with increasing variability of resource inflow and  $\mu$ . The initial proportion of cooperators is set to 0.5. Here red indicates  $fc = 70\%$ , while green indicates 100% cooperation

### 3.2 Competition of Multiple Strategies

It is likely that resource users choose extraction strategies that are not confined to a set of a single cooperative and defector strategy but vary more widely. To assess how a fairness norm affects the evolution of individual extraction strategies and thus total extraction behavior of the community we developed an ABM that allows for agents with multiple strategies. Agents are initialized with a random strategy drawn

from a uniform distribution on the interval  $[0, \psi * E_{OA}/N]$ ,  $\psi \geq 1$ , where  $E_{OA}$  is the aggregate extraction level that leads to open access resource exploitation. Interactions between agents are modeled as in §2, through random pairs that one at a time step update their utilities and strategies. An agent is identified as a defector when his payoff is larger than the payoff of the opponent. Thus in this case the definition of a defector becomes dynamic and relative to the actual opponent. The magnitude of the ostracism is a function of the proportion of cooperators which is determined in the following way: cooperators are all agents who follow the norm, i.e. have an extraction strategy that is equal or lower than the socially acceptable extraction level:

$$f_c = \frac{\sum_{j=0, j \neq i}^N n_j}{n} \text{ for which } e_j \leq e_{eff} \quad (10)$$

The ostracism is normalized using the highest payoff available in the population at the current time step,  $\pi_{max}$ , instead of the (unique) defector payoff as in the game theoretic version presented in §2.

$$U_d = e_d * \left( \frac{f(E, R)}{E} - w \right) - \omega(f_c) * \frac{\max\{\pi_d - \pi_j, 0\}}{\pi_{max}} \quad (11)$$

We allow for random mutations where one agent chooses a new random extraction strategy at a specified mutation rate. Figures 7 and 8 show the results of the competition of multiple strategies with different strengths of ostracism expressed through the  $\delta$  parameter of the ostracism function. Each square in Figure 7 is respectively the mean or the standard deviation of 100 runs for each  $\delta$  value. With increasing strength of the social norm there is a clear transition from a defector state where total effort is at open access to a Cooperator equilibrium with effort levels at or below the socially optimal level. This transition is signaled by an increase in the standard deviation of total effort which peaks around delta values of 0.5. This is a region of bistability where some simulations result in an open access total effort, while others result in lower total extraction levels (Figure 7). The average number of strategies present in the population also increases during the transition and decreases significantly with an increase in  $\delta$ . Thus, with increasing strength of ostracism conformity is increased. The peak of total payoffs occurs around delta values of 1 where total effort is at the socially optimal level (0.48). With an increase in the strength of the ostracism the population converges to extraction levels that are below socially optimal indicating that the fairness norm is effective in restraining individual resource extraction but can lead to sub-optimally low resource exploitation. The latter case is reminiscent of a partial tragedy of the anticommons, where too much regulation leads to too much inhibition of extractive activities, with respect to the optimum

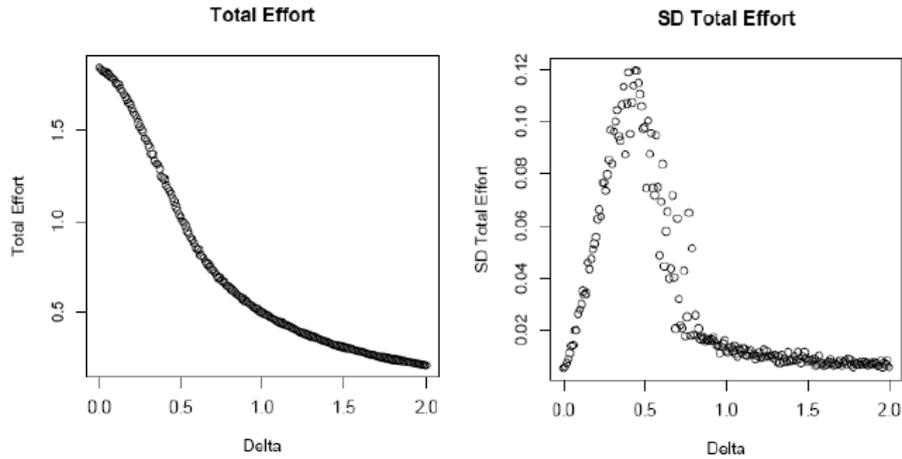

Figure 7: Average total effort (left) and standard deviation (right) of 50 runs for each  $\delta$  value. Simulation initialized with 50 random uniformly distributed strategies. Mutation rate is 1 mutation every 10 time steps

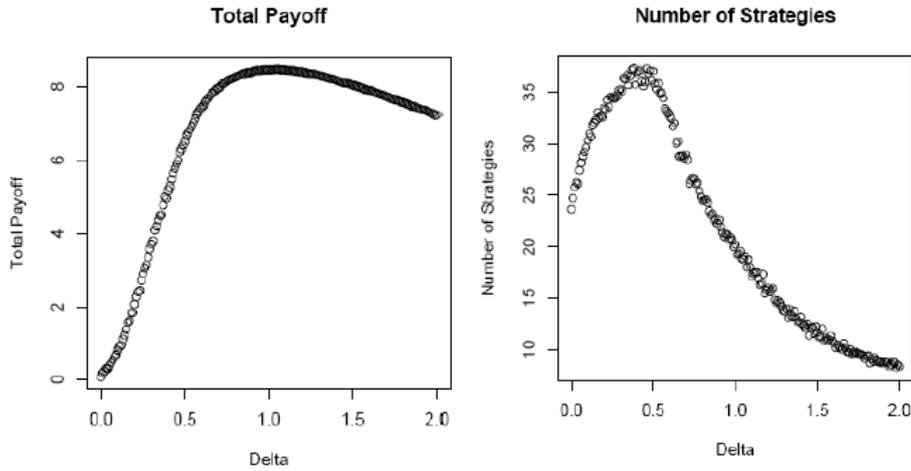

Figure 8: Average total payoff (left) and number of surviving strategies (right) of 50 runs for each  $\delta$  value. Simulation parameters as in Figure 7

## 4 Concluding remarks

In this paper we have developed a model of community-based appropriation of a common pool resource in the presence of a norm allowing discrimination of behavior. Individuals departing from what the community considers as acceptable behavior (in terms of non-excessive resource extraction), are therefore subject to what we call equity-driven ostracism: a denial of support by the cooperating community which has tangible consequences on the wealth of the norm violators. Such retaliation, which may be thought of as consisting of spiteful actions (e.g. denied machinery lending and crop destruction) or social reprobation (e.g. negative gossiping and refusal to share information), depends on two factors. On the one hand the relative strength of the community of norm followers, since a larger community is assumed to be more effective

at ostracizing defectors. Secondly, the intensity of the response by the community is assumed to be higher the larger the entity of the defection, which is revealed by the differences in the yield of the production, as the latter depends on the amount of resource extraction. Another noteworthy feature is that we model the coupled socio-economic and ecological dynamics of a common pool resource, such as water, that provides benefits indirectly by being utilized as an input of production rather than for its intrinsic value (as is the case for fish in fisheries). Sections 2 and 3 considered cooperation as the outcome of an evolutionary process, with successful strategies spreading in the population as a result of a process of imitation. Analytical derivations and evidence from numerous simulations allowing for complex interactions and resource dynamics lead to the following conclusions:

- a) A Defector equilibrium, unregulated by the norm, is achieved only for low initial frequency of cooperators; interestingly, the basin of attraction shrinks as the gap between  $e_d$  and  $e_c$  (i.e.  $\mu$ ) increases, due to resource stock effects. All other initial conditions lead either (b) or (c), even when most agents initially do not abide to the norm.
- b) A Cooperator equilibrium, where all abide to the norm, arises so long as the defector's payoff is bounded above by the full compliance ostracism costs:  $\omega(1) > \pi_d(e_d, R_{eff})$ . This is the case when the effort differences between cooperators and defectors are not too large.
- c) Stable coexistence obtains when effort differences between cooperators and defectors are pronounced, sparing the latter from being eradicated:  $\omega(f_c^*) = \pi_d(e_d, R^*)$
- d) Under variable resource replenishment rates, cooperators thrive better, because they can still benefit from the social capital provided by other cooperators despite a reduction in average resource volumes, while the defectors experience a decrease in payoffs to  $\tilde{\pi}_d(e_d, \tilde{R})$ .
- e) A competition of extraction strategies will lead to open access extraction efforts when the social norm is weak; however the system will approach optimal extraction levels rapidly when the strength of the social norm increases.

The model presented here focuses on agents harvesting from a renewable resource while facing a social norm discerning between acceptable and excessive behavior. Notwithstanding its simplicity, it allows to identify three regimes for the stationary state of the evolutionary dynamics, depending on the initial number of norm followers, the effort gap between types and the community effectiveness in enforcing the norm. In (a) the resource is severely over-harvested, a situation reminiscent of the tragedy of the commons; in (b) the resource is efficiently shared by a homogeneous population restricting use to the collectively optimal level; in (c) both type coexist and manage to partially internalize the externality. Where the system ultimately converges depends on the path followed.

## Appendix

### Stability analysis

In this section we shed light on the monomorphic equilibria found in §2.3 by means of the stability analysis based on the linearization matrix  $J$  of the system (2)-(6):

$$J = \begin{bmatrix} \frac{\partial \dot{f}_c}{\partial f_c} & \frac{\partial \dot{f}_c}{\partial R} \\ \frac{\partial \dot{R}}{\partial f_c} & \frac{\partial \dot{R}}{\partial R} \end{bmatrix}$$

$$= \begin{bmatrix} \varphi[\omega'(f_c)(f - f_c^2) + \omega(f_c)(1 - 2f_c) + (2f_c - 1)\pi_d] & 0 \\ nR(e_d - e_c) & \frac{-dkR^{k-1}}{R^{k_{max}}} - E \end{bmatrix}$$

where  $\varphi = \frac{\pi_d(e_d, R) - \pi_c(e_c, R)}{\pi_d(e_d, R)}$

The bottom two entries of  $J$  are unambiguous in sign, which is respectively positive and negative. Therefore, for stability considerations, whether an equilibrium is stable depends on  $\partial \dot{f}_c / \partial f_c$ . When  $f_c = 0$ , it reduces to  $\varphi \pi_d < 0$ , so  $tr(J) < 0$  and  $Det(J) > 0$ , which means both eigenvalues of  $J$  are negative real numbers and the Defector equilibrium is a stable attracting fixed point. It can be shown that, when  $f_c = 1$ ,  $\partial \dot{f}_c / \partial f_c = \varphi(\pi_d - \omega(1))$ , which is negative provided that  $\omega(1) > \pi_d$ . Thus, the Cooperator equilibrium is stable so long as the defector's payoff is bounded above by the full compliance ostracism costs.

### Alternative ostracism function

The specification employed in Figure 3 may be too favorable for the cooperators, since even at low  $f_c$  they are able to exert some degree of pressure on the defectors. It may be more realistic to consider the case where the community of norm followers becomes effective in ostracising the violators only beyond some threshold. For instance, this may happen when at least half of the population is comprised of cooperators, as in Figure 9. While a full account of the impact of utilizing this function in place of the

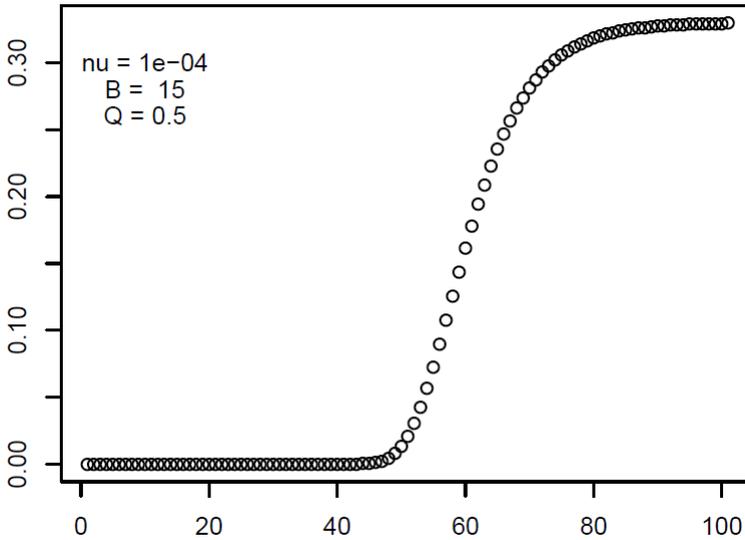

Figure 9: A threshold ostracism function

one depicted in Figure 3 is not yet available, we have initial evidence suggesting that the qualitative features found in §2.3 still hold, despite a reduced parameter space supporting the Cooperator equilibrium.
